THE RELATIONSHIP BETWEEN CONVERSION FACTORS AND HEALTH: EVIDENCE FROM THE READY-MADE GARMENT WORKERS IN BANGLADESH

Abstract

This study examined the association between health condition and conversion factors (i.e. environmental, individual and social) among workers in the ready-made garment (RMG) industry in Bangladesh. It used data gathered from a cross-sectional survey of 775 RMG workers in the Dhaka and Narayanganj districts. Using multiple logistic regression, the study found that: (i) achieving good health among RMG workers is hindered by various factors including high job-related demands, high noise levels, workplace crowding, heavy workloads, and low level of educational attainment; (ii) job-related rewards and marital status have contributed to achieving good health; (iii) health condition of workers is worse for women than for men; and (iv) poor health condition was more prevalent among the oldest age group than in the lowest age category. The main contributions of this research are: (i) this study develops a comprehensive framework to determine the factors affecting the health condition of manufacturing workers in general, and RMG workers in particular; and (ii) this study examines the effects of both psychosocial and physical working conditions on the health of RMG workers.

JEL Classification: J00, I01, I31.

Key Words: Capability Framework; Conversion Factors; Health; RMG Workers; Bangladesh.

1. Introduction

In 2010, Bangladesh ranked second among ready-made garment (RMG) exporters in the world (Bangladesh Garments Manufacturers and Exporters Association, 2016).

The contribution of this sector to the national economy is enormous, leading the government to widely promote the industry. However, the reputation of the industry has been undermined by adverse working conditions including low wages, long working hours, tiring work and exposure to workplace violence.

It is in this climate that worker safety, security and health became serious concerns following the collapse of a factory building located in Rana Plaza, Savar (a sub-district

1
2
3 of Dhaka), in April 2013 (Yardley, 2013). The lack of even minimum safety standards
4
5 at the workplace – as well as irregular and meagre pay for workers – have been
6
7 viewed as a serious concern. There is a general recognition of the need for revision
8
9 and improvement. After two such industrial disasters (Tazreen Fashion in 2012 and
10
11 Rana Plaza in 2013), working conditions in the RMG industry seemed to improve.
12
13 More social compliance practices were introduced under the purview of the Ministry
14
15 of Labour and Employment, Government of Bangladesh (GoB) and the International
16
17 Labour Organisation (ILO). However, the implementation of minimum wage law is
18
19 still dubious (Asadullah & Wahhaj, 2016). Shortcomings are noted in the process of
20
21 revising the Bangladesh minimum wage on a regular basis. For example, the
22
23 government did indeed raise the minimum wage of the RMG industry four times in the
24
25 last 20 years (i.e. in 1994, 2006, 2010 and 2013), but this was not done on a regular
26
27 basis taking into account market value. Instead, it was only revised in response to
28
29 massive public protests by the workers (Asadullah & Wahhaj, 2016).
30
31
32
33
34

35
36 Previous studies have identified various health problems among industrial workers in
37
38 general, and garment workers in particular (De Silva et al., 2013; Gupta et al., 2015).
39
40 Karasek and Theorell (1990) argued that poorly-educated and low-skilled workers are
41
42 extremely susceptible to poor health. As a result of high physical demands in the
43
44 manufacturing industry, blue-collar workers experience more health-related problems
45
46 than white-collar workers (Lahelma et al., 2012). Therefore, it is necessary to identify
47
48 the factors that are critical to improving the health of garment workers, and remove
49
50 hindrances to good health. Apart from benefiting the workers, such measures will also
51
52 have a positive impact on firm productivity.

1
2
3 There is now considerable study done on the physical and occupational health
4 problems faced by garment workers in Bangladesh (Gupta et al., 2015; Islam et al.,
5 2014; Ahmed and Raihan, 2014). Overcrowded work environments, verbal and
6 physical abuse, high noise levels, inadequate ventilation, and the overall physical
7 environment of the workplace seriously affect worker health. While these accounts are
8 rich, they have not taken into account psychosocial working conditions and their effect
9 on worker health. One study did broach psychosocial working conditions, but only
10 focused on workers in one firm (Steinisch et al., 2013). Furthermore, physical working
11 conditions and health outcomes were not explored in that study.

23

24 In addition to examining subjects from a large sample of workers, we use the
25 Capability Approach (CA) advanced by Sen (1992, 2001) which offers room to
26 analyse the well-being of workers as an outcome variable (Mabsout, 2011).
27 Functioning refers to “constitutive of a person’s being” (Sen, 1992). Health is one of
28 the basic functioning variables. Robeyns (2003) expanded the CA of Sen (2001) by
29 discussing the conversion factors that are essential to achieving this functioning.
30 Therefore, all conversion factors play important roles in either hindering or expanding
31 the capabilities of humans. The relationships between the variables are shown in the
32 conceptual framework (Figure 1). All three conversion factors (environmental,
33 individual and social) have been included to examine whether or not they influence
34 health outcomes. In other words, the main aim of this study is to examine the effect of
35 the conversion factors as expounded by the CA on the health condition of workers in
36 the RMG industry in Bangladesh.

1
2
3 The findings using the CA provide alternative policy interventions that could be used
4 to improve working conditions of RMG workers in Bangladesh. Improvements in the
5 health of workers will also improve the public image of garment factories in
6 Bangladesh, which largely export to European and North American markets (Ahmed
7 and Ahmed, 2011). The total number of people working in the RMG industry in
8 Bangladesh was 4 million in 2015, which makes it one of the largest employers in the
9 country (Bangladesh Garments Manufacturers and Exporters Association, 2016).
10 Clearly, the long-term sustainability of garment industry employment depends heavily
11 on worker health – therefore, research into the relationship between conversion factors
12 and their effects on the health of workers is of paramount importance.

37 **2. Methodology**

38 There has been increasing interest in the impact of working conditions on worker
39 health, following the expansion in global value chains and the tightening of trade
40 regulations on working conditions at host-sites in major markets (e.g. Barrientos et al.,
41 2011). However, most researchers focused on case studies using qualitative analysis.
42 In contrast, this study is based on a quantitative analysis using a large data set, and
43 makes a significant contribution by complementing previous research.

54 *2.1 Conceptual Framework*

1
2
3 We adapted the capability framework proposed by Robeyns (2005), which in turn was
4 based on the principles of Sen's (2001) Capability Approach. Capabilities can be
5 expanded or constrained depending on conversion factors (Tao, 2010), as they are
6 means by which individuals can convert resources to functions. According to Robeyns
7 (2005), capabilities consist of a combination of functioning – either potential or
8 achieved – and can be categorised into: (i) individual conversion factors (e.g.
9 intelligence, skills, age, gender and education); (ii) environmental conversion factors
10 (e.g. geographical location, logistics and infrastructure); and (iii) social conversion
11 factors (e.g. social norms and gender relations, roles and identities). The role of
12 conversion factors is critical in converting the characteristics of goods into individual
13 functions, and helps translate the conditions into capabilities.

Figure 1 illustrates how conversion factors contribute to shaping the capability set of workers with information on three distinct kinds of indicators: (i) environment (psychosocial working conditions, physical working conditions and workload); (ii) individual (age, education, and gender), and (iii) social (marital status).

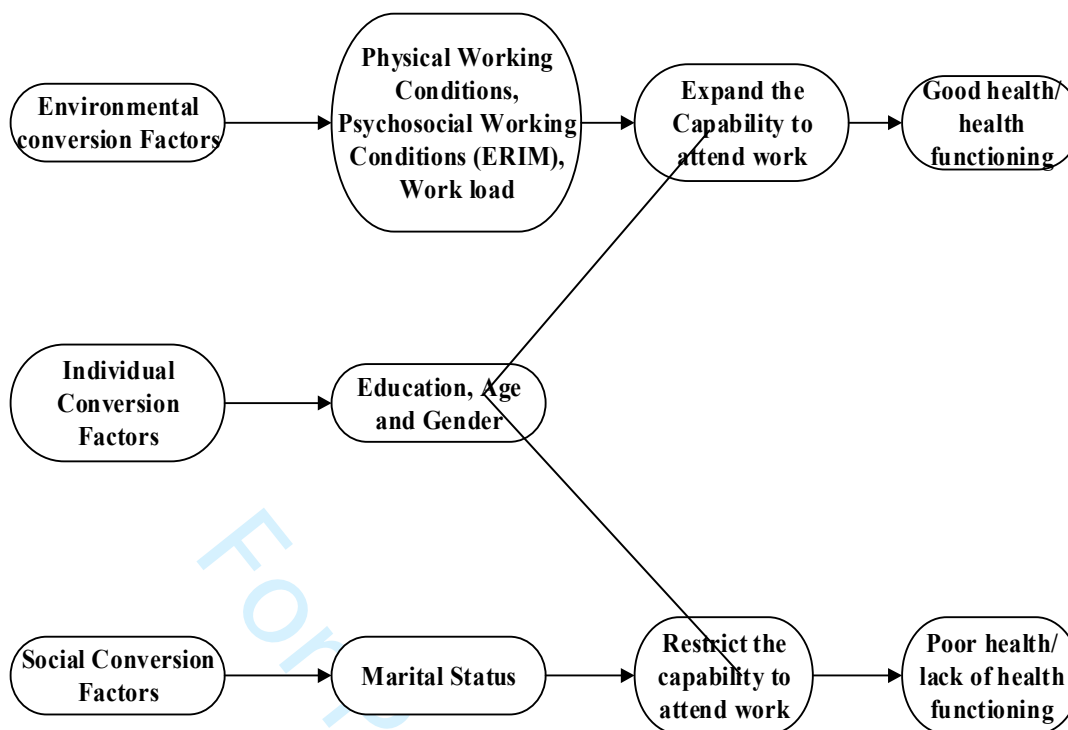

Figure 1: Conceptual Framework

We have chosen proxies to measure conversion factors (environmental, individual and social) and determine the relationship between them and health functioning. Capabilities refers to the freedom or opportunity enjoyed by an individual to perform work; that is, by being healthy. Conversely, the conversion factors may restrict capability, and result in poor health functioning. All three conversion factors can either restrict or expand capability. On the one hand, psychosocial and physical working conditions could contribute to illness or poor health of workers, as well as affect the choices or freedom of workers. On the other hand, these environmental conversion factors could contribute to good health. Individual conversion factors (e.g. education, age and gender) and social factors (e.g. married or unmarried) could improve the health of workers. As the determinants of health functioning are the conversion factors, we attempt to identify the conversion factors that contribute to

1
2
3 positive health functioning among low-wage garment workers in Bangladesh. This is
4
5 illustrated in Figure 1.
6
7

9 2.2 *Conversion Factors and Effort-Reward Model*

11 The Effort-Reward Imbalance Model (ERIM) developed by Siegrist et al. (2004) is
12 based on two components – efforts and rewards. It posits that when efforts (e.g.
13 pressure to finish work on time) are not sufficiently rewarded (e.g. an adequate salary,
14 good promotion prospects, job security and recognition), it may cause distress to
15 workers and eventually weaken their health. Nieuwenhuijsen et al. (2010) considers
16 adverse working conditions as a major determinant of worker health. ERIM
17 emphasises the environmental factors in the workplace – when these factors are
18 favourable, workers are likely to experience reasonable levels of good health; whereas
19 if these factors are unfavourable, worker health could be adversely affected. However,
20 the model did not take into account individual and social factors. To address that
21 shortcoming, this study mainly adapted the capability frameworks of Robeyns (2005)
22 and Sen (2001), and also incorporated some questions from the ERIM questionnaire to
23 formulate a more comprehensive set of proxies on environmental factors that affect
24 workplace settings.

40
41
42
43

44 According to Danielsson et al. (2015) the workplace constitutes two factors: (i)
45 psychosocial; and (ii) physical environment; and both contribute to stress at the
46 workplace. The importance of psychosocial working conditions in enhancing worker
47 health has been well recognized (e.g. Nieuwenhuijsen et al., 2010; Steinisch et al.,
48 2013). In addition, researchers also identified workplace noise (Jahncke et al., 2011)
49 and crowding (De Croon et al., 2005) as environmental factors that can create stress at
50
51
52
53
54
55
56
57
58
59
60

1
2
3 the workplace; these have been used as measures of the physical working environment
4 (Loscocco and Spitze, 1990). Excessive noise is detrimental to health and could pose a
5 threat to the quality of life of workers, as it causes stress at the workplace (Chauhan
6 and Pande, 2010; Evans and Johnson, 2000). Given the importance of both
7 psychosocial and physical working conditions in the RMG industry of LDC, we
8 included both variables in the conceptual framework as environmental conversion
9 factors. The use of individual conversion factors in this study is similar to previous
10 studies (e.g. Otto and Ziegler, 2006; Robeyns, 2003). Marriage is a social institution,
11 and Robeyns (2005) considered social institutions as a social conversion factor.
12 Therefore, in the proposed conceptual framework, environmental conversion factors
13 comprise psychosocial and physical workplace environments; individual conversion
14 factors are age, gender, and education; and marital status is considered to be the social
15 conversion factor.

2.3 Data, Sample Size and Sampling

36
37 In light of the lack of data, we opted to collect primary data on garment workers in
38 Bangladesh. The dataset was collected via fieldwork conducted between May and
39 November 2015, using a structured questionnaire as the primary instrument. In order
40 to obtain an appropriate sample size, the following formula was used (Lind, Marchal,
41 & Wathen 2007):

$$n = \frac{\pi(1 - \pi)Z^2}{E^2}$$

42 Where n is the minimum size of the sample, π (0.50) is the population proportion, Z is
43 the standard normal value corresponding to the desired level of confidence and E is

1
2
3 the maximum allowable error. Based on the formula for sample size, $Z = 1.96$ (95%
4 confidence level), $\pi = 0.5$ and $E = 5\%$. The above function is appropriate for infinite
5 population size sampling and a minimum sample size of 385. According to Krejcie
6 and Morgan (1970), this figure is an appropriate sample size, so it can be argued that
7 the outcome of the current study should not raise concerns of bias due to the sampling
8 procedure used.
9
10
11
12
13
14
15
16
17

18 *Sampling Frame*

19
20 The study used multistage random sampling to collect data. Garment factories are
21 located in nine districts in Bangladesh (Department of Inspection for Factories and
22 Establishments, 2015). We have divided the whole of Bangladesh into nine clusters,
23 as they are homogeneous in nature. After that, we chose the districts of Dhaka and
24 Narayanganj randomly (i.e. through a lottery method) following the database of the
25 Department of Inspection for Factories and Establishments (DIFE) under the Ministry
26 of Labour and Employment.
27
28
29
30
31
32
33
34
35
36

37 According to the Bangladesh Bureau of Statistics (2013a), Dhaka district has 41
38 Thana¹ and six Upazila². We randomly selected five Thana (namely Mirpur, Gulshan,
39 Mohammadpur, Tejgaon Industrial Area and Tejgaon) and one Upazila (namely
40 Savar) using a lottery method. There are 1961 factories in Dhaka district, and 734
41 factories in Narayanganj district (Department of Inspection for Factories and
42 Establishments, 2015). Next, using the database of DIFE, we randomly selected 7
43 factories from each of the six administrative units – for a total of 42 factories. Finally,
44
45
46
47
48
49
50
51
52

53
54 ¹ Dhaka City Corporation is divided according to the area controlled by a Police Station, this is called a Thana.
55 It includes the city corporation area declared by the Ministry of Local Government.

56 ² Upazila is the second lowest administrative unit in Bangladesh. Dhaka District comprises Dhaka City
57 Corporation area and other areas outside the city corporation boundary.

1
2
3 using the factory registers, we selected 420 workers (i.e. 10 workers from each
4 factory).³ We collected 400 valid responses using face-to-face interview technique.
5
6
7
8

9 The same sampling frame and mode were used to decide the sample size for
10 Narayanganj District. According to the Bangladesh Bureau of Statistics (2013b),
11 Narayanganj District has five Upazila and six municipalities. We selected five Upazila
12 (namely Narayanganj Sadar, Bandar, Rupganj, Sonargaon, and Araihaazar) and then
13 selected seven factories randomly from each administrative unit, for a total of 35
14 factories. Using the factory registers, we chose 12 workers from each factory – for a
15 total of 420 workers. We collected 375 valid interviews from these 420 randomly
16 selected respondents. Overall, 775 interviews were completed, out of which the
17 respondents were 560 female and 215 male.⁴

23
24
25
26
27
28
29
30
31
32

33 2.4 Analytical Technique 34

35 The logit model is a commonly used model when the response variable is a
36 dichotomised binary response. According to Greene (2003), logistic regression is used
37 to predict the probability of an event occurring or not occurring, by fitting data to a
38 logit form. The equation for the logit model is as follows:
39
40
41
42
43

$$44 \text{Logit}(p) = \ln\left(\frac{p}{1-p}\right) = \beta_0 + \beta_1 X_1 + \dots + \beta_k X_k \dots (1)$$

45
46
47
48
49
50
51

52 ³ It is important to mention that we also used an application that can generate random numbers, using top and
53 bottom numbers of the population without replacement.

54 ⁴ It is to be noted that the computer application “Rossman/Chance Applet Collection” was used to generate
55 random numbers for selecting factories and workers. The purpose of the study was explained to the participants,
56 they were assured of confidentiality before starting the interviews, and written consent was obtained from each
57 respondent.
58
59
60

1
2
3 Where $p = \text{Prob}(Y = 1)$ is the probability that an individual reports absenteeism due to
4 poor health, β_0 is the intercept parameter, and β_1 is the regression coefficients of the
5 i^{th} variable in the model.
6
7

8
9 The description of the selected variables used for the study is shown in Table 1.
10
11

12 13 *Dependent Variable*

14
15 Sickness absence or absenteeism due to poor health is a global measure of health
16 status and an indicator of social, psychological and physical functioning for working
17 people (Marmot et al., 1995). It is evident that the longer the period of sickness
18 absence, the poorer the health status (Niedhammer et al., 2013). Occurrence of
19 sickness absence happens as a consequence of several work-related factors, and it is
20 one of the proxies for gauging the health status of workers. We asked the respondents
21 whether they had been absent from work due to illness in the previous year.
22
23
24
25
26
27
28
29
30
31
32

33 This measure was dichotomized by grouping response scores into (i) health
34 absenteeism occurrence as a category of poor health, and (ii) health absenteeism non-
35 occurrence as a category of good health. Therefore, the dependent variable is scored as
36 follows:
37
38
39
40

$$41 \quad Y = 1, \text{ if a worker is absent due to poor health; } Y > 0$$

$$42 \quad Y = 0, \text{ otherwise; } Y = 0$$

43 44 45 *Independent Variables*

46 47 *Psychosocial Working Conditions*

48
49 We used the shortened version of the ERIM questionnaire that had previously been
50 used for analysing the health outcomes of RMG workers (Dragano et al., 2010;
51 Steinisch et al., 2013). In line with the previous studies, we measured efforts based on
52
53
54
55
56
57
58
59
60

1
2
3 the perceptions of the workers – including physical demands and time pressure.
4
5 Reward was measured using five aspects: social support, salary, recognition,
6
7 promotion prospects and job security. We recorded all affirmative answers as
8
9 ‘strongly disagree’ to ‘strongly agree’ to maintain the consistency of the respondents’
10
11 scores in a five-point Likert scale (1 = ‘strongly disagree’ and 5 = ‘strongly agree’).
12
13 The full list of items is provided in Appendix A.
14
15
16
17

18 *Physical Working Conditions*

19
20 A five-point Likert Scale was used to measure stressors in the physical working
21
22 environment – noise and crowdedness. Respondents were asked to rate noise levels
23
24 and the degree of crowding at their workplace, with categories ranging from 1 for
25
26 ‘very low noise’ to 5 for ‘very high noise’ and the same range for ‘very low crowding’
27
28 to ‘very high crowding’. In addition, workers were also asked whether the rest breaks
29
30 provided by the factories were adequate or not, thus providing a dichotomous variable
31
32 where 1 indicated ‘sufficiently adequate’ and 0 indicated ‘not adequate at all’.
33
34
35
36

37 Paul-Majumder (1996) found that long working hours in the RMG industry was the
38
39 factor most adversely affecting the health status of workers. The RMG industry has
40
41 often been criticised for its long working hours (Yunus and Yamagata, 2012), and
42
43 studies have identified this as a factor causing psychosocial illness among the RMG
44
45 workers (Padmini and Venmathi, 2012). Hence, we have included industry-specific
46
47 working conditions (working hours per week as a proxy to measure workload) in this
48
49 study.
50
51
52
53

54 *Individual and Social Conversion Factors*

Education, gender and age were used as categorical variables and individual conversion factors, while marital status (which is also a categorical variable) was considered as a social conversion factor.

Table 1: Definition and Measurement of the Variables

Variables	Definition, classification and measurement
Health status	Poor health = 1; good health = 0
Job-related rewards	Continuous variable (z score derived from the EFA)
Job-related demands	Continuous variable (z score derived from the EFA)
Level of noise	Very low level of noise = 1; low level of noise = 2; average level of noise = 3; high level of noise = 4; very high level of noise = 5
Level of crowdedness	Very low level of crowdedness = 1; low level of crowdedness = 2; average level of crowdedness = 3; high level of crowdedness = 4; very high level of crowdedness = 5
Adequacy of rest period	Adequate rest period = 1; not adequate rest period = 0
Workload	Categorical variable. 40 – 53 hours (low workload) = 1; 54 – 59 hours (average workload) = 2; 60 – 62 hours (high work load) = 3; 63 – 84 (very high workload) = 4
Education	Level of educational attainment. No education = 0; some primary = 1; some secondary = 2; higher secondary and above = 3
Age	Completed years and further split into five age cohorts. 13 – 18 = 0; 19 – 23 = 1, 24 -29 = 2; 30 -34 = 3; ; 35 and above = 4
Gender	Female = 1; male = 0
Marital status	Unmarried = 0; married = 1; divorced = 2; widowed = 3

Exploratory Factor Analysis

An exploratory factor analysis (EFA) was conducted in order to determine the potential elements of the psychosocial working environment. We used orthogonal rotation (Varimax) which allows for correlation between potential factors. To test the sensitivity of the analysis, we ran additional analyses based on oblique rotation (Promax). Both indicated the correlation of potential factors.

At the beginning, we identified factors based on the eigenvalue exceeding 1. The EFA suggested two factors on the basis of this criteria. We label the first factor as *job-related rewards* that comprises four items: support, recognition, adequate salary, and promotion prospects. The second factor is labelled as *job-related demands* and consists of two items: physical demands and time pressures. Importantly, the items that belong to a particular factor have loadings of 0.5 or higher (see Table 2). The factors identified via EFA are very similar to the factors found by Steinisch et al. (2013), but they had instead identified three factors. The loadings of the items of our study do not allow for three factors. Sampling might be the reason for this result, as the abovementioned study was based on only one garment factory. Cronbach's alpha was computed for each of the identified factors, with job-related rewards at 0.616 and job-related demands at 0.552.

Table 2: EFA of the 7 Items on Psychosocial Working Conditions or Work Stress (N = 751)

Psychosocial working conditions items (work stress)	Factor Loading (Eigenvalue)	
	<i>Job-related rewards (1.91)</i>	<i>Job-related demands (1.40)</i>
Physical demand	0.080	0.821
Time pressure	0.044	0.817
Support	0.605	-0.116
Recognition	0.670	-0.068
Promotion	0.682	-0.061

2.4.1 Model Specification

According to the capability framework, we estimate the health status equation as follows:

$$H_i = \beta_1 + \beta_2 JR_i + \beta_3 JD_i + \beta_4 noise_i + \beta_5 crowd_i + \beta_6 restp_i + \beta_7 wl_i + \beta_8 education_i + \beta_9 age_i + \beta_{10} gender_i + \beta_{11} ms_i + \varepsilon_i \dots (1)$$

JR and *JD* denote job-related demands and job-related rewards respectively, that we derive from the EFA; *noise*, *crowd* and *restp* represent the level of noise, crowding and adequacy of rest breaks respectively; *wl* denotes working hours per week (proxy to measure workload); *education*, *age* and *ms* (*marital status*) are measured as categorical variables. *Gender* denotes as binary variable where female is coded as 1 and male is coded as 0.

3. Results and Discussion

The correlation matrix of the independent variables is shown in Appendix B. The Variance Inflation Factor (VIF) and Tolerance Statistics (TS) also show that there is no multicollinearity problem among independent variables (see Appendix C).

Table 3 presents the percentage distribution of all categorical variables. We were not able to make the percentage distribution of *JR* and *JD* with the health conditions, as both are continuous variables. Chi - square test is used to test the significant differences among the various categories and sub groups of variables. Table 3 shows that the majority of workers who reported high levels of noise, crowdedness and inadequacy of rest period were in poor health. It is also evident from Table 3 that the majority of workers who reported poor health status (61.66%) have a very high level of workload (working hours per week of 63 to 84 hours). While exploring the effects of education, we can see that those who have no education reported poor health status more in terms of percentage distribution (69.23%). Only 39.71% of the lowest age category (13-18) reported poor health, in contrast to 68% among the oldest age

category. Marital status is found to be an important factor for determining health condition, with a higher percentage of divorced workers reporting poor health compared to other categories. We also found a gender difference among those who reported poor health – 54.11% of female and 33.95% of male workers reported poor health status. A previous study that examined the association between poor health and psychologically adverse working conditions found that 67.9% of female and 56.6% of male workers were in poor health (Paul-Majumder, 2003). This may partly be explained by the impact of some recent developments in the sector, such as changes made to the minimum wage law (which was amended three times) and continuous international pressure on health and safety issues in the RMG industry. These factors appear to have made wages and working conditions more favourable compared to the past.

Source: Authors' Survey

48.52% of the respondents reported that they were absent from work during the previous year due to illness, indicating that poor health is a factor for nearly half of the workers. Based on the diagnostic test of logistic regression (Hosmer-Lemeshow test with a p-value 0.758), we could say that our model fits the data well.

1
2
3 Table 4 presents the results of a multiple logistic regression analysis against all
4 independent variables, using a dummy dependent variable (1, 0) for the question of
5 whether respondents were absent or not absent from work due to poor health. The first
6 and second columns present estimates of equations (1) with coefficient values and Odd
7 Ratio (OR) values. The logistic regression reveals a negative and statistically significant
8 relationship between job-related rewards and poor health of RMG workers. It suggests
9 that a one unit increase of job-related rewards decreases the log odds of being in poor
10 health by -0.354 of a unit. This is in contrast with the study conducted among 332
11 workers of a garment factory based in the capital city of Dhaka (Steinisch et al., 2013).
12 The difference might be the result of different sampling frames. It is worthwhile to
13 mention that high work-related rewards were found to be an important component in
14 other studies that looked at high-income countries (Lau, 2008). The OR of job related
15 rewards was 0.701.
16

28
29
30
31
32

33 There is a positive and significant association between high job-related demands and
34 poor health. According to equation (1), a one unit increase of job-related demands
35 increases the log odds of poor health by 0.200 of a unit. The OR is 1.222, which suggests
36 that those who reported high job-related demands are likely to have poor health status.
37 This finding is consistent with another study of the RMG industry in Bangladesh
38 (Steinisch et al., 2013) where they found a positive association between poor health and
39 high job-related demands.
40
41
42
43
44
45
46
47
48
49

50 Regarding noise levels, a very low level is used as the reference category. Noise level
51 was found to be highly significant at average, high and very high levels, and the
52 relationship with absenteeism due to poor health was positive. This indicates that higher
53
54
55
56
57
58
59
60

1
2
3 noise levels affected the health conditions of RMG industry workers. Note that
4 coefficients and OR increased when moving from average to high, and from high to very
5 high noise levels ($OR_{\text{average noise level}} = 2.211$, $OR_{\text{high noise level}} = 2.541$, $OR_{\text{very high noise level}} =$
6 5.463). This indicates that higher noise levels are significantly associated with poor
7 health of workers. Therefore, we can conclude that the higher the level of noise, the
8 higher the probability of absenteeism due to poor health. A high level of noise is one of
9 the factors responsible for poor health status of workers. This result is consistent with
10 previous findings on industrial noise being an underlying cause of poor health among
11 workers in American manufacturing companies (Cohen, 1974) and among European
12 blue-collar workers (Melamed and Green, 1991).

18
19
20
21
22
23
24
25

26 Workplace crowding also showed a positive relationship with absenteeism due to poor
27 health. Very low crowding was used as the reference category, and crowding in the
28 workplace was found to be consistently significant – starting from very low all the way
29 to very high levels. It should be noted that when workplace crowding shifted from very
30 low to low levels, from low to average levels, from average to high levels, or from high
31 to very high levels, then both the coefficients of crowding levels from average to very
32 high-level crowding and the adjusted OR increased simultaneously. The OR of crowding
33 at high and very high levels of crowdedness were 4.727 and 5.029 respectively. This
34 finding is consistent with the outcomes of other studies (Lamminpää et al., 2012;
35 Pekkarinen et al., 1979) that noted crowding as a contributing factor detrimental to
36 health.

55
56
57
58
59
60

1
2
3 Adequacy of rest breaks was found significant in model 1 at the 5% level. It suggests that
4
5 a one unit increase of adequacy of rest breaks decreases the log odds of being in poor
6
7 health by 0.554 of a unit. This outcome has been endorsed by Taylor (2005).
8

9 Working hours per week was used as a proxy in order to estimate workload, and the
10
11 results suggested that workload influenced the health conditions of workers. We found a
12
13 positive and statistically significant relationship between workload and poor health
14
15 conditions of workers. We used low workload as the reference category. The result
16
17 suggests that average and high workloads increase the probability of being in poor health
18
19 when compared against low workload. The OR also indicates that the chance of being in
20
21 poor health is 2.351 higher for those who have very high workload comparing with those
22
23 who have low workload, similar to the findings of previous studies (Bannai and
24
25 Tamakoshi, 2014; Paul-Majumder, 1996).
26
27
28
29
30

31 From the analysis, this study reveals that individual conversion factors such as education,
32
33 age and gender are associated with health condition. From Table 4, it can be seen that the
34
35 adjusted OR for no education, primary education and secondary education stood at
36
37 5.855, 4.955 and 3.248 respectively, against the reference category that represents the
38
39 highest level of educational attainment (higher secondary level and above). The effect is
40
41 found to be the highest among those with no education, in contrast to those with the
42
43 highest level of education. In addition, the groups with some primary and secondary
44
45 levels of educational attainment also reported a higher probability of being in poor health
46
47 when compared to the group with the highest level of education. This finding is also
48
49 consistent with the previous literature (Adams et al., 2003; Ross and Wu, 1995). In
50
51 looking at gender where male is used as the reference category, the results suggest a
52
53 positive and significant association. It implies that the chances of reporting poor health
54
55
56
57
58
59
60

1
2
3 are 2.227 times higher for a female worker in comparison to a male worker. This is
4
5 consistent with the previous findings in RMG settings in Bangladesh (Paul-Majumder,
6
7 1996). Furthermore, age was found to be an important factor. Those who are in the oldest
8
9 age category have 3.061 times higher chance of reporting poor health condition than
10
11 those who belong to the lowest age category, a finding which is consistent with existing
12
13 literature (Khan and Flynn, 2015).
14
15
16
17

18 Turning to marital status, being unmarried is used as the reference category. Although
19
20 being married decreases the logarithmic probability of being in poor health, it is found
21
22 statistically significant at a 10% level. Hence, the effect is not much stronger compared
23
24 to the effects of other significant variables. This result is also consistent with the findings
25
26 of previous studies (Khan and Flynn, 2015).

4. Conclusion

This paper examined the relationship between health status and the conversion factors of environment, individual and social conditions of RMG workers in Bangladesh, using a comprehensive framework based on the Capability Approach of Sen (2001), Robeyns (2005) and the Effort-Reward model of Siegrist et al. (2004). It employed cross-sectional data comprising 560 female workers and 215 male workers in the Dhaka and Narayanganj districts to find out the factors affecting health conditions of RMG workers.. The dependent variable was whether the respondents were in good health or poor health. The study considered those who were absent from work due to illness as being in poor health, and identified the factors that were responsible for poor health or that hindered the achievement of good health. Multiple logistic regression was used for data analysis.

The results showed that the following conversion factors constrained the capability and choice of workers in achieving good health functioning: high job-related demands, high noise levels, high crowding in the workplace, increased workload, and low level of educational attainment. However, it also found that high job-related rewards and being married expanded the capability to achieve a level of good health functioning. Furthermore, the study revealed that being a female worker increased the probability of having poor health condition. Poor health was prevalent among the oldest age group of workers, which is also a consequence of ageing.

1
2
3
4
5 The empirical evidence supports the role of conversion factors to increase the
6 capability of RMG workers in enhancing health functioning. Hence, environmental,
7 individual and social conversion factors play a significant role in shaping the health
8 status of RMG workers in Bangladesh. By examining how the conversion factors
9 shape the health status of RMG workers, the study firstly confirms that both
10 psychosocial and physical working conditions are crucial to enhance the health status
11 of RMG workers. Secondly – in particular for RMG workers – environmental
12 conversion factors matter more than individual and social conversion factors. This
13 study confirms the fact that women face more difficulty in achieving good health
14 status than men, which also concurs with previous findings (Paul-Majumder, 1996;
15 Paul-Majumder, 2003). Clearly, women are at a disadvantage in achieving capability
16 and health functioning. Previous studies have used either psychosocial working
17 conditions (Steinisch et al., 2013) or physical working conditions. We have instead
18 combined both psychosocial and physical working conditions – something which has
19 been seldom used in the literature in examining the health conditions of
20 manufacturing workers in general, and RMG workers in particular.
21
22
23
24
25
26
27
28
29
30
31
32
33
34
35
36
37
38
39
40

41 A number of policy implications can be drawn from this study. First, employers or
42 owners need to be aware of psychosocial working conditions – by reducing the high
43 physical demands of jobs and time pressure, they can improve the poor health status
44 of RMG workers. Second, another set of psychosocial working conditions that
45 employers or owners should be aware of includes good promotion prospects,
46 recognition of work, adequacy of salary and support – improving these conditions
47 may facilitate improvements in the health status of workers. Third, reducing noise
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 levels and workplace crowding may contribute to better conditions and a reduction in
4 absenteeism due to poor health. Fourth, reducing working hours is likely to have a
5 positive impact on improving the health status of RMG workers. Fifth and lastly, firm
6 owners need to take necessary steps to provide proper health services, in particular to
7 women workers.
8
9
10
11
12

13
14
15 Although the results of this study are robust, they should be treated with caution since
16 this study relies on a cross-sectional rather than a panel dataset – the latter of which is
17 important to establish causality. There was also no comparison made between the
18 health status of workers in the RMG industry against other manufacturing sectors.
19
20 Future studies should focus on following a sample of RMG industry workers over
21 time and attempt to compare findings with research on other manufacturing sectors. In
22 addition, the influence of environmental, individual and social conversion factors
23 could also be measured separately both for physical and mental health. Moreover,
24 future studies in RMG settings also can use different measures of health outcome (e.g.
25 biomarkers, self-reported health status) instead of the proxy of absenteeism due to
26 poor health, in order to see whether the results differ or remain the same.

Appendix A: Items on Psychosocial Working Environments Used in This Study

Items of measuring psychosocial working conditions	Full questions
Physical Demand	My job is physically demanding
Time Pressure	I am under constant pressure due to heavy workload
Support	I receive adequate support in difficult situations
Salary	Considering all my efforts my salary is adequate
Recognition	I receive the recognition I deserve for my work
Promotion	My job promotion prospects is good
Job Security	My job security is good
