Abstract

Background. It has been found that alterations in passive muscle properties can may be affected by associated with low back pain (LBP), and these may be responsible for the altered gait parameters often observed in subjects with back pain LBP. The purpose of
the present study was to assess total hip and passive hip extensor moments in people
with or without LBP during the hip flexion component of walking.

**Methods.** 52 subjects volunteered for this study (LBP low back pain group, \( n = 25 \) (male \( n = 13 \), female \( n = 12 \)), control group (NBP), \( n = 27 \) (male \( n = 15 \), female \( n = 12 \))). Passive
hip moments were measured calculated using an adapted force transducer during supine
testing. A biomechanical model and predictive equation were used to calculate passive
hip moments during walking. Total hip moments were measured calculated with the use
of a 9 camera, 3-D motion-capture system.

**Findings.** Independent samples t-tests demonstrated no significant differences between
groups for gait parameters or hip or knee angles. Results of the ANOVAs demonstrated
significant differences in passive hip flexor moments during the second half of hip flexion
\((P < 0.05)\). There were significant differences in the peak of hip flexor moments, in
moments at hip neutral, and in passive moments during the second half of hip flexion \((P
< 0.05)\). There were also significant differences in hip power and work done during peaks
of power absorption and the second peak of power generation \((P < 0.05)\).

**Interpretation.** The present data demonstrates that subjects with LBP low back pain have
altered passive hip extensor and total hip moments, power and work done during walking
compared with healthy controls. Biomechanical models should include individual
measurements of passive joint moments.

Passive elastic contribution of hip extensors to joint biomechanics during
walking in people with low back pain
Introduction

Low back pain (LBP) is one of the leading causes of disability globally [1]. Clinical assessments of LBP patients often include tests of hip extensor extensibility [2]. Tests can include assessment of knee extension angle and sacral angle, the sit and reach test [3], and the straight leg raise test [3, 4]. However, the relevance of hip muscle extensibility to LBP and any relationship to movement remains unclear [5]. There is a growing interest in including more comprehensive assessments of joint and muscle resistive properties, due to the lack of consensus with assessing extensibility alone [6, 7].

Joint passive resistance is a property of the non-contractile tissues, such as the tendon, sarcolemma, endomysium, perimysium and epimysium [6, 8-10], structural proteins such as titin [11], and inactive muscle fibres. Active resistance is a property of contracting muscle fibres. Some investigators report musculotendinous extensibility being moderately related to passive stiffness, and weakly related to active stiffness [9]. An investigation by Halbertsma et al. [7], reported an association between hamstring extensibility and LBP, but no differences in passive stiffness between LBP patients and controls. Overall, there is a lack of agreement in the literature as to whether passive muscle resistance is related to extensibility [9, 12]. Further, any relationship between extensibility, passive and active stiffness and activities of daily living (ADLs) in LBP patients remains to be determined.

It has been found-reported that muscle resistive properties can be affected by LBP may be altered in subjects with LBP [6, 13, 14], and these may-could be responsible for
the reduced leg swing, step length and gait velocity often observed in LBP subjects when compared with healthy controls [15-18]. During the late swing phase of walking, the activation of biceps femoris is increased in LBP [18], indicating altered active factors. Identifying alterations to passive or active components may be a useful tool for the clinical assessment of LBP, and the first stage in developing effective physical therapy-based treatment strategies.

The purpose of the present study was to assess total hip and passive hip extensor moments in people with LBP during the hip flexion component of walking, and to compare them with pain-free controls. Passive hip moments were calculated as a product of hip and knee angle using a dynamic biomechanical model. Further comparisons were made of total hip power and work done during hip flexion and the complete gait cycle.

2 Methods

2.1 Participants

Fifty-two subjects volunteered for this study. Subjects were excluded if they were pregnant or had any tumours, rheumatological or musculoskeletal disorders, tuberculosis, or an injury or infection of the spine, hips or knees during the 3 months prior to their participation. Subjects were also excluded if they had a history of any dislocation or surgery of the spine or lower limbs. Female subjects were only eligible for testing during the 7 days following the first day of menstruation, to control for any potential effects of the ovarian cycle.
Subjects meeting the inclusion criteria were divided into groups according to if they had suffered with chronic, non-specific low-back pain (LBP group, \( n = 25 \) (male \( n = 13 \), age = 34 (SD 8.53) years female \( n = 12 \) age = 30 (SD 7.96) years) for at least 6 weeks, including at least one episode during the week of the study, or were back-pain-free (NBP group, \( n = 27 \) (male \( n = 15 \), age=29 (SD 7.78) years, female \( n = 12 \), age=33 (SD 8.78) years). Subjects in the NBP group needed to have been without back pain during the 6 months prior to the study.

Following consent to participate, subjects were required to complete a medical screening form and International Physical Activity Questionnaire (short form) (IPAQ-SF). LBP subjects were required to complete a Roland Morris Disability Questionnaire (RMDQ) and to rate their level of pain on a visual analogue scale (VAS). During the recruitment process the groups were matched for age, body mass, gender and physical activity habits (type and experience). The study was approved by the ethics committees of both the University of Roehampton and the British College of Osteopathic Medicine.

2.2 Experimental Setup

Passive hip extensor moments were measured calculated during leg raising tests using an adapted force transducer, comprising a bi-axial cantilever load cell (QLA263, Futek, Irvine, US), and 2 analogue electro-inclinometers (PTAM27, ASM, Moosinning, Germany). The force transducer was inserted into a custom-built ankle brace designed to house the transducer with minimal friction, whilst maintaining the ankle in neutral. Four knee braces were pre-formed to secure the knee at 180, 170, 160 and 140 degrees,
where 180 degrees refers to the knee in full extension. An additional two electro-
inclinometers were secured using straps to the thigh and shank, to measure hip angle
and angular acceleration, and knee angle, respectively. Two single differential surface
electromyography (EMG) electrodes (SX230, Biometrics, Newport, UK), were placed
over the biceps femoris and rectus femoris, in accordance with the SENIAM guidelines
for electrode placement. The EMG signals were used for real-time feedback to ensure
no activity, and not for subsequent analysis.

The analogue signals from the load cell were pre-amplified (CSG110, Futek, Irvine,
US) with 15 VDC for each input and analogue-digital converted. All analogue signals
from the load cell and inclinometers were acquired at 50 Hz, and from the EMG electrodes
at 1000 Hz, using a data acquisition unit (Datalink, DLK900, Biometrics, Newport, UK).
Load cell and inclinometer data was digitally filtered at 2 Hz using a low-pass Butterworth
filter, and saved to a personal laptop computer (Dell Precision, M4500, Dell, Bracknell,
UK) for processing with Matlab programming software (Version 7.3, Mathworks, Natick,
US).

Subjects were required to lie supine on a massage table. In accordance with the
procedures of Lee and Munn [19], the test leg was passively raised 10 times to
precondition the tissues, and to account for variability in activity levels between subjects
immediately prior to testing (the test set-up is shown in figure 1). Supine passive leg
raises were performed 3 times with each of the 4 knee braces, with 1 minute rest between
tests with the same knee brace, and 2 minutes between different braces. During testing
the subject was required to verbally indicate if and when they felt an onset of stretch-
related pain. Each test would cease upon the onset of pain or deviations in EMG muscle activity above resting baseline level.

Figure 1. Subject test set-up for passive hip moment assessment, showing placement of force transducer, ankle brace and one of the 4 knee braces used to maintain the knee at a predetermined angle (180 degrees in the example above).

Total hip moments were measured during level walking with the use of a 9 camera, 3-D motion-capture system (T-series, Vicon, Oxford, UK) and 2 force plates (9281CA, Kistler, Winterthur, Switzerland). 35 retro-reflective markers were placed on each subject in accordance with the placements used by previous researchers [20-22]. Motion capture data was sampled at 100-Hz and force plate data at 1000-Hz. The data was stored on a personal computer (Dell Precision, M4500, Dell, Bracknell, UK). Data was initially assessed via the Nexus software programme (Vicon Nexus version 1.8,
Vicon, Oxford, UK), before being transferred to Microsoft Excel (2010, Microsoft-Excel, Redmond, US) and Matlab for further processing.

Subjects were required to walk along a 10-metre walkway in view of the motion capture cameras and over the force plates at their normal walking speed. The tester observed foot contact onto the force plates and ensured a minimum of 5 walks contained both left and right clear foot strikes. Once this was achieved the tester completed preliminary processing to ensure all markers were still visible in a minimum of 5 of the walks for each leg. If this was not the case further tests were carried out until sufficient complete data was available. Walking was at each subject’s normal pace without reasonable likelihood of fatigue during testing.

2.3 Data Processing

A data processing pipeline was created in Vicon Nexus to perform standard data modelling of the walking trials. The pipeline included Woltring filtering and gap filling. Following determination of marker trajectories data was smoothed using a low-pass Butterworth filter at 6 Hz. Total moment-angle data for the hip was established for each complete gait cycle, and data was used from the first 5 complete tests on each leg. The coefficient of multiple correlation (CMC) of the moment-angle curves were calculated. Where CMC values were less than 0.8 the moment-angle curves were visually assessed for any outlying curve, with outliers replaced by other gait cycle data for that subject, or removed and the mean and CMC recalculated based upon the remaining data.
coefficient of variation (CV) was also calculated to assess intra-subject gait cycle variability.

Passive hip moments are a property of the length of moment arm and the amount of soft tissue, and so data was normalised to body mass and height. Hip moment-angle data was originally determined from 0 degrees (hip neutral) to maximum hip range of motion. Because the number of samples was reduced as hip angle increased, due to individual limitations in range of motion, the range 0 to 60 degrees was used for analysis as a majority of subjects achieved this. Passive hip extensor moments were calculated based upon the dynamic biomechanical model developed by Lee and Munn [19]:

\[
M = F_x y_f + F_y x_f + m_{leg} \ddot{x}_{cg} y_{cg} - (m_{leg} g + m_{leg} \ddot{y}_{cg}) \dot{x}_{cg} - m_{leg} k^2 \dddot{\theta}
\]

where \(F_x, F_y\) are the forces applied to the leg to flex the hip joint, \(X_f, Y_f\) are the locations of force application to the leg, \(m_{leg}\) is the mass of the leg, \(g\) is acceleration due to gravity, \(x_{cg}, y_{cg}\) refer to the location of the centre of mass of the leg and \(k\) is the radius of gyration. \(\ddot{x}_{cg}, \dddot{y}_{cg}\) refer to the acceleration of the leg centre of mass, and \(\dddot{\theta}\) is the angular acceleration of the leg. Dempster [23] body segment parameter ratios were used for both the total and passive moment calculations.

Passive hip moments are a property of the length of moment arm and the amount of soft tissue, and so data was normalised to body mass and height. Hip moment-angle data was originally determined from 0 degrees (hip neutral) to maximum hip range of motion. Because the number of samples was reduced as hip angle increased, due to individual limitations in range of motion, the range 0 to 60 degrees was used for analysis.
as a majority of subjects achieved this. The ensemble mean curve from of 3 leg raises, smoothed using cubic spline interpolation and fitted with an exponential function, was used for further analysis.

To establish a predictive equation for passive hip extensor moments based upon a combination of hip and knee angles, 3-D surface plots were generated for assessing the changes in hip moments with hip angle, and at different knee angles. In agreement with other researchers [19], passive hip moments were found to increase exponentially as a function of hip angle. By introducing a variable knee angle component, it was found that this contributed a linear component to the equation. A surface fitting programme was written for Matlab, and visual and residual analyses used to determine the most appropriate equation coefficients for the individual datasets. From the present investigation, the following equation was developed to predict passive hip moments ($M_{\text{passive}}$) during flexion:

$$M_{\text{passive}} = a \cdot \theta_{\text{knee}} + b \cdot \exp(c \cdot \theta_{\text{hip}}) + d$$

where $\theta_{\text{knee}}$ is the angle at the knee, $\theta_{\text{hip}}$ the angle at the hip, and $a$, $b$, $c$, and $d$ are the equation coefficients.

Passive hip moments and 95% confidence intervals were recalculated from hip neutral to maximum hip flexion angle, using the derived predictive equation. Root mean squared error (RMSE) and adjusted $r$-squared were calculated to assess goodness of fit of each surface-plot.
Hip moments were calculated within the Vicon Nexus Plug-in Gait software, using the conventional gait model, based upon the Newington-Helen Hayes model. Total hip power was calculated based upon hip angular velocity and total hip moments. All data was subsequently normalised to body mass and height. Total hip moments were calculated at the peak hip flexor moment (FL), and the two hip extensor peaks (Ext1, Ext2). Total hip power was calculated at the two peaks of power generation (H1, H3) and peak of power absorption (H2). Mechanical work done at H1 and H3 was calculated by integrating the complete positive portions of the corresponding power generation curves. Work done was also calculated for the full negative power absorption curve (H2). Passive hip extensor moments and total hip moments, power and work done were additionally calculated for the portion of the gait cycle corresponding to hip flexion, between hip neutral and maximum hip flexion angle. Scores for the RMDQ were calculated as the sum of ticked statements. Scores for both RMDQ and VAS were entered into a Microsoft Excel spreadsheet for further analysis. Physical activity data was used to ensure matching of subjects in LBP and NBP groups.

2.4 Statistical Analysis

Independent t-test A mixed-model analysis of variance (ANOVA) was used to compare within gait cycle peaks and degrees of hip flexion between LBP and NBP group data using SPSS (version 24, IBM Statistics, U.S.). Post hoc analyses for between groups comparisons were performed using independent samples t-tests where significant interactions were determined. Passive hip extensor moments and total hip moments,
power and work done were compared at 25% increments of hip flexion, between neutral
and maximum hip flexion. Total hip moments were additionally compared at FL, Ext1 and
Ext2, and total power and work done were compared at H1, H2 and H3. Additional
comparisons included age, gender, body mass, physical activity type and duration,
walking speed and step length gait parameter data, maximum hip flexion angle, hip
extension angle and knee angle, assessed using independent t-tests. CMCs and CVs
were used to assess intra-subject gait cycle characteristics. RMSE and the adjusted r-
squared were used to assess goodness of fit of the predictive equation coefficients for
calculating passive moment contributions. Normality of data was assessed using
Shapiro-Wilk tests, and the alpha level for all tests was set at 0.05.

3 Results

Subjects in the LBP group reported occurrence of back pain for 6.97 (SD 5.98) years with
a range of 6 weeks to 30 years. RMDQ scores were 3.92 (SD 3.1) and VAS scores were
5.06 (SD 2.27). Independent samples t-tests demonstrated no significant differences
between LBP and NBP groups for age, gender, body mass (within gender), for any of the
gait parameters walking speed or step length measured (P > 0.05). There were no
significant differences (P > 0.05) in any of the physical activity parameters
measured/calculated, which included walking (13.6 (SD 18.3) hours per week LBP, 9.9
(SD 12.9) hours NBP), moderate intensity exercise (6.9 (SD 11.0) hours per week LBP,
4.1 (SD 5.6) hours NBP) and vigorous exercise (6.7 (SD 8.7) hours per week LBP, 5.1
(SD 3.4) hours NBP).
The CMC means were 0.955 (SD 0.037) for LBP and 0.937 (SD 0.051) for NBP, respectively. The CV means were 21.4% (SD 11.6) and 26.3% (SD 13.9), for LBP and NBP, respectively. The RMSE was 0.016 (SD 0.008) Nm/(kg* m) for LBP and 0.017 (SD 0.007) Nm/(kg* m) for NBP. The adjusted r-squared values were 0.889 (SD 0.081) for LBP and 0.896 (SD 0.075) for NBP. There were no significant differences in hip or knee angles between groups (P > 0.05).

During early stance phase total hip moments were negative (hip extensor moments) and increasing to zero, becoming positive at 18% GC for LBP and 22% for NBP (figure 1). Throughout mid-to-late stance total hip moments were positive (hip flexor moments), with a peak (FL) at approximately 50% GC for both groups. From late stance to mid-swing, total hip moments were positive but decreasing towards zero. There were no statistically significant interaction effects in the total hip flexor (FL) or extensor moments peaks (Ext1, Ext2) or their timings (F(1.571,155) = 3.019, P = 0.065 > 0.05, table 1) or their timings (F(1.599,158) = 0.368, P = 0.645) (figure 2). There was no main effect of group (F(1.99) = 0.208, P = 0.649). During the hip flexion component of the gait cycle, there was no statistically significant interaction effect in total hip moments (F(2.064,204) = 0.823, P = 0.444) (table 2). There was no main effect of group (F(1.99) = 0.012, P = 0.913).
For passive hip moments, there was a significant interaction effect of group and percentage of hip flexion for passive hip moments ($F(1.751,173) = 9.316, P < 0.000$) and a statistically significant main effect of group ($F(1,99) = 6.597, P = 0.012$).

Passive hip moments decreased throughout hip flexion, demonstrating increased extensor moments (figure 3), with no significant differences between groups at hip neutral or 25% ($P > 0.05$). From 50-100% of hip flexion, passive moments were significantly more negative in LBP subjects ($P < 0.05$), demonstrating greater extensor moments. At maximum hip flexion, passive hip extensor moments were 46.6% and 39.4% of total hip moments, for LBP and NBP, respectively. Passive hip extensor and total hip moment mean, standard deviation and results of the independent t-tests are shown in table 2.
Table 1. Variable data for complete gait cycle. NS (not significant) indicates ANOVA P > 0.05 with post hoc tests not indicated. Statistically significant results are denoted with an asterisk(*).

Figure 3.2. Mean passive hip extensor moments with 95% confidence intervals in LBP and NBP groups during hip flexion from neutral to maximum hip flexion.

Table 2. Passive hip extensor and total hip moments (Nm/(kg*m)) during hip flexion, from neutral to full hip flexion. NS (not significant) indicates ANOVA $P > 0.05$ with post hoc tests not indicated. $P$-values included represent results of post hoc independent t-tests. Statistically significant results are denoted with an asterisk (*).
Total hip power was generated during the first 20% of the gait cycle, with an initial peak of power generation (H1) during early stance phase in both LBP and NBP (Figure 3). There was a statistically significant interaction of group and peak of hip power ($F(1.353,134) = 4.366, P = 0.027$) but no main effect of group ($F(1,99) = 0.06, P = 0.807$).

There were no significant interactions of angle at peak ($F(1.526,151) = 0.863, P = 0.398$). The first peak of power generation (H1) occurred significantly earlier in LBP than NBP ($8.2(4.5)\%$, $10.0(4.4)\%$, for LBP and NBP, respectively, $P = 0.049$), with no difference in power ($P > 0.05$, Table 1, Figure 4). The first peak of power generation (H1) occurred at...
8.2 (SD 4.5) %, and 10.0 (SD 4.4) % of gait cycle, for LBP and NBP, respectively, with no significant differences in timing or power ($P > 0.05$, Table 1, Figure 4). The hips then absorbed power, with a peak of power absorption (H2) during mid-stance. The peak of power absorption at H2 was significantly greater in LBP than NBP ($-0.520$ (SD 0.231) W/(kg$^\ast$m), $-0.429$ (SD 0.212) W/(kg$^\ast$m), for LBP and NBP, respectively, $P = 0.041$), with no difference in timings between groups ($P > 0.05$). Total hip power was positive from approximately 50% to 85% GC in both groups, as the hip flexors generated power from the end of stance phase through to the end of swing phase. Power generation peaked at toe-off and the initiation of swing phase, at approximately 60% GC (H3). The second peak of power generation at H3 was significantly greater in LBP than NBP (0.844 (SD 0.298) W/(kg$^\ast$m), 0.736 (SD 0.235) W/(kg$^\ast$m) for LBP and NBP, respectively, $P = 0.045$), with no difference in timings between groups ($F(1.526,151), = 0.863, P = 0.398$). Total hip power became negative from 90-100% of the GC in LBP, as the hip muscles absorbed power at the end of the swing phase and initial foot contact, whereas in NBP they were positive.
Figure 4. Mean total hip power with 95% confidence intervals in LBP and NBP groups during gait cycle.

For power during the hip flexion component of gait (figure 5), ANOVA results demonstrated a significant interaction of group and time \( (F(2.264,224) = 3.228, P = 0.036) \) but no main effect of group \( (F(1,99) = 2.538, P = 0.114) \). Post hoc analyses determined that total hip power was significantly greater \( (P = 0.012) \) in LBP subjects when the hip was in neutral \( (LBP = 0.717 (0.300) \text{ W/(kg*m)}, \text{NBP} = 0.583 (0.22) \text{ W/(kg*m)}) \). There were no statistically significant differences between groups at any other percentage of hip flexion assessed \( (P > 0.05) \). Mean, standard deviation and results of the independent t-tests for hip flexion are shown in table 3.
Figure 54. Mean hip power with 95% confidence intervals in LBP and NBP groups during hip flexion from neutral to maximum hip angle.

Table 3. Total hip power (W/(kg\(^*\)m)) during hip flexion, from neutral to full hip flexion. Statistically significant results are denoted with an asterisk (*)..

Discussion

The present study found no statistically significant differences in hip and knee angles between groups. Values of passive hip extensor moments, and total hip moments, power and work done for NBP subjects were similar to those reported elsewhere [24]. Other investigators have reported alterations in hip and knee angles during walking in LBP subjects compared with healthy controls [25-27]. The most likely cause of increased passive moments in LBP is an increased passive resistance of the hip extensor and knee flexor muscles, such as the bi-articular hamstrings muscles. However, a previous study using the same subjects demonstrated no significant differences in passive moments between groups. Because passive hip moments increase with hip angle in an exponential manner, it is likely that small increases in hip angle have a considerable influence on passive moments during walking, as observed in the present study. It is also plausible that individual alterations and interactions of joint angles and passive moments may be masked by averaging individual and group leg data. Alternatively, the difference in passive moments equates to a maximum of 3 Nm in absolute rather than normalised figures, which may be statistically significant but of little, if any, clinical relevance. Altered passive moments occurred without differences in total moments.

Peak hip flexor moments (FL) were greater in LBP than NBP, during the late stance phase of gait. Hip flexor moments were also greater as the hip passed through neutral during the early swing phase, with no differences in hip moments during the remainder of hip flexion. Greater total hip flexor moments coincided
with increased hip flexor power generation and mechanical work done in LBP compared with controls, as the hip passed through neutral in early swing phase. Increased hip moments may coincide with increased muscle activation, with increased power generation either as a pre-emptive strategy to overcome the increased passive resistance later in the swing phase, or to increase hip-pelvic-lumbar stability.

Power absorption and work done at H2 were significantly greater in LBP than NBP. The H2 power curve occurs during the stance phase of gait, as the hip flexors eccentrically contract to stabilise the pelvis and support the trunk, preventing backwards movement of the trunk relative to the pelvis. Power generation and work done at H3 were also greater in LBP than NBP, and occurs during the late stance (pre-swing) phase of gait, as the hip flexors contract concentrically to pull the leg forward and facilitate toe-off. This coincided with greater power generation and work in LBP than NBP as the hip moved through neutral. Although there were no group differences in the H1 peak of power generation that follows initial contact in early stance, power generation occurred earlier in LBP than NBP.

The results of the present study demonstrate increased passive extensor moments in LBP, with no differences in total moments during the same portion of hip flexion. Whether the passive moments contribute to total moments, thereby reducing the need for active contraction and promoting efficiency, or if values of total moments should be altered due to the influence of greater passive moments, is not currently understood [24]. Alternatively, altered joint angles, and therefore passive moments, later in the swing phase may follow the increased total power generation from the hip flexors during early...
swing, directly following toe-off. In this case, increased passive moments may be due to increased joint angles, resulting from greater momentum of the hip where active power generation is greater in LBP with no differences in passive moments following toe-off. Greater momentum of the swinging limb could cause greater hip flexion angles, contributing to greater passive resistance, and therefore higher passive moments. The lack of difference in total moments may reflect reduced active components late in swing, or be due to total moments being miscalculated due to lack of account of passive influences in inverse dynamic modelling. Despite our lack of understanding regarding the mechanisms and interactions of the passive and active components, it is clear that the passive component is considerable, and should not be overlooked in future models of dynamic movements.

LBP subjects in the present study reported RMDQ scores that were low (3.92 (SD 3.1)) compared with other studies, VAS scores were considered moderate (5.06 (SD 2.27)), and similar to those reported elsewhere [28-35]. Although self-reported pain is a subjective measure, subjects in the studies where VAS and RMDQ scores were higher were recruited from physical therapy and rehabilitation clinics [28, 29, 31]. Overall, the findings in the present study remain appropriate to the population assessed. Whilst LBP severity and disability may be lower than in subjects attending rehabilitation clinics, there were clear adaptations in gait to modify passive and active joint biomechanics compared with healthy controls.

The present study indicates that passive moments may be influenced without affecting total joint moments. Specifically, it is plausible that LBP may affect the structural components of muscle tissue, or alternatively results in subtle interactions of joint angle
and moments during movement, sufficient to influence passive components without affecting total moment. There may be further interactions between LBP, passive moments, total power and total work done, which affect accelerations and energy efficiency for movement. From a clinical perspective, an assessment of passive biomechanics will be useful to help understand which tissue types are influenced by LBP, on a case-by-case basis. Findings suggestive of structural adaptations will necessitate a muscle-targeted therapy, such as stretching or strengthening exercise. Conversely, if joint kinematics are altered, this indicates the active component of the muscular system may have been affected, necessitating a therapy that targets neuromuscular improvements, such as muscle activation timing and magnitude, and the specific fibres recruited during movement.

A limitation of the current study was the measurement of hip passive moments during hip flexion only. In previous studies [24, 36, 37], researchers averaged hip moments during flexion and extension, and reported only a small underestimation of moments during flexion, and overestimation during extension. However, in the present study it was considered more appropriate to determine accurate values of passive hip extensor moments, for integration into the hip flexion model during walking, rather than over- or underestimating moments. Future studies would benefit from direct measurement of both passive hip extensor and hip flexor moments to model the complete gait cycle accurately in the sagittal plane.

Hip extensor moments were 46.6% and 39.4% of total hip moments for LBP and NBP, respectively, at maximum hip flexion angle. This finding demonstrates that passive structures may interact with active components, have a considerable influence on total
hip moments during walking [24], and should be integrated into future biomechanical
models. Whether it is appropriate to add passive moments to total moments, or to
subtract them, or if there is a more complex interaction between passive and active
components to total moments is not currently understood [24] and therefore warrants
further investigation.

Conclusions

The present data demonstrates that subjects with LBP have altered passive hip extensor
moments and total hip moments, power and work done during walking, compared with
healthy controls. Although it is not possible to extrapolate cause and effect relationships,
rehabilitation programmes for LBP patients should differentiate between the active,
neuromuscular components of movement, and the passive components. Biomechanical
models should include individual measurements of passive joint moments. The approach
used in the present study may be a useful measurement model for clinicians assessing
low back pain.
